Alamos, New Mexico, USA.

3 Two-dimensional electromagnetic particle-in-cell simulations are performed
4 to study the temporal development of an ion Bernstein instability driven by
5 a proton velocity distribution with positive slope in the perpendicular ve-
6 locity distribution function $f_p(v_\perp)$, where \perp denotes directions perpendic-
7 ular to the background magnetic field \mathbf{B}_0 . The instability grows at propa-
8 gation angles nearly perpendicular to \mathbf{B}_0 , and at frequencies close to the har-
9 monics of the proton cyclotron frequency. The simulated field fluctuation spec-
10 trum shows peaks near the first few harmonics of the proton cyclotron fre-
11 quency and resembles observations of ULF waves, commonly referred to as
12 fast magnetosonic waves, near the geomagnetic equator in the terrestrial mag-
13 netosphere. This growing mode may play an important role in the transverse
14 heating of thermal protons and the acceleration of radiation-belt electrons.

1. Introduction

Enhanced field fluctuation spectra with peaks at frequencies close to the proton cyclotron frequency and its harmonics up to the lower hybrid resonance frequency have been observed near the geomagnetic equator of the terrestrial magnetosphere at radial distances between 2 and 8 R_E [Russell et al., 1970; Perraut et al., 1982; Santolik et al., 2002]. The typical amplitude of the associated magnetic fluctuations is $0.03 \sim 0.2$ nT [Perraut et al., 1982], which suggests $\delta B/B_0 \sim 10^{-4}$ (\mathbf{B}_0 is the background geomagnetic field). The waves propagate nearly perpendicular to \mathbf{B}_0 , are primarily confined within $2 \sim 3^\circ$ of the geomagnetic equator, and are mainly observed in the afternoon and pre-midnight sectors. Observations [Perraut et al., 1982; Boardsen et al., 1992; Meredith et al., 2008] and theoretical studies [Gul'elmi et al., 1975; McClements et al., 1994; Chen et al., 2010] suggest that the waves are driven by energetic protons at energies of tens keV which have ring-like distributions with $\partial f_p(v_\perp)/\partial v_\perp > 0$ ($f_p(v_\perp)$ is the perpendicular velocity distribution function).

These waves were first referred to as “equatorial noise” [Russell et al., 1970], but more recently have been called “fast magnetosonic waves” because observations show that the wave magnetic field component is polarized along the background geomagnetic field [Perraut et al., 1982] and the ratio of the electric field intensity to that of the magnetic field intensity is in good agreement with the theoretical values for fast magnetosonic waves at wave normal angles near 90° [Boardsen et al., 1992]. These enhanced fluctuations are believed to play an important role in the transverse heating of thermal protons [Horne

35 *et al.*, 2000] and the acceleration of radiation-belt electrons [*Horne and Thorne*, 1998;
36 *Horne et al.*, 2007; *Shprits*, 2009; *Bortnik and Thorne*, 2010].

37 *Denton et al.* [2010] provide further insight into these enhanced fluctuations. Using
38 both Cluster observations in the plasma sheet boundary layer and linear kinetic disper-
39 sion theory, they demonstrated that the waves are excited by a ring-type property of
40 the proton velocity distribution. They also found that the wave properties change sig-
41 nificantly with the proton beta (β_p). At $\beta_p \ll 1$, these fluctuations are predominantly
42 electrostatic, suggesting that these waves are more accurately described as ion Bernstein
43 waves [*Janhunen et al.*, 2003; *Ashour-Abdalla et al.*, 2006]. As β_p approaches unity, the
44 waves develop a strong electromagnetic component. The excited magnetic field fluctu-
45 ations have components in both the perpendicular and parallel directions (with regard
46 to \mathbf{B}_0), but the perpendicular fluctuations are larger. More interestingly, the parallel
47 magnetic fluctuations δB_{\parallel} become dominant when β_p is further increased, which resem-
48 bles the fluctuations referred to as fast magnetosonic waves that are observed near the
49 geomagnetic equator in the terrestrial magnetosphere. These results have been confirmed
50 by *Gary et al.* [2010], who further pointed out that the maximum instability growth rate
51 decreases with increasing electron-to-proton temperature ratio.

52 Although some simulation studies have addressed the ion Bernstein instability in the
53 electrostatic limit [*Lee and Birdsall*, 1979; *Janhunen et al.*, 2003], no simulations have
54 addressed the fully electromagnetic properties of this instability in the high β_p regime
55 appropriate for the magnetosphere. The present study carries out two-dimensional (two
56 spatial dimensions, but all three velocity components retained) electromagnetic particle-

57 in-cell (PIC) simulations to investigate the properties of the ion Bernstein instability
 58 driven by proton distributions with $\partial f_p(v_\perp)/\partial v_\perp > 0$ and $\beta_p \sim 1$. The PIC code used is
 59 a reduced version of the three-dimensional PIC model in *Liu et al.* [2006] and has been
 60 successfully applied to the study of particle energization by oblique inertial Alfvén waves
 61 in the auroral region [*Seyler and Liu, 2007*]. The simulation results demonstrate that the
 62 ion Bernstein instability grows at propagation angles nearly perpendicular to \mathbf{B}_0 , with a
 63 fluctuating field spectrum with peaks at frequencies close to the first few harmonics of the
 64 proton cyclotron frequency, in agreement with recent theory [*Denton et al., 2010; Gary*
 65 *et al., 2010*] and observations of fast magnetosonic waves.

2. Simulation Results

66 The two-dimensional simulation domain lies in the $x - y$ plane and the background
 67 magnetic field is in the y direction. Periodic boundary conditions are used in both di-
 68 mensions. Due to the nearly perpendicular propagation of the instability, we choose
 69 $L_x = 9.6\lambda_i$, $N_x = 128$, $L_y = 64\lambda_i$, and $N_y = 64$, where $\lambda_i = \sqrt{m_p/n_0\mu_0e^2}$ is the ion iner-
 70 tial length. Other relevant parameters are $m_p/m_e = 100$, $\omega_p/\Omega_p = 15$ ($\omega_p = \sqrt{n_0e^2/\epsilon_0m_p}$
 71 is the proton plasma frequency and $\Omega_p = eB_0/m_p$ is the proton cyclotron frequency), and
 72 the time step length is $\delta t\Omega_p = 0.001$. The present simulation has 2000 ions and 2000
 73 electrons in each cell. The reduced proton-to-electron mass ratio and the relatively small
 74 ω_p/Ω_p used here are to enable a large time step. Although they slightly affect the prop-
 75 erties of the ion Bernstein instability, they do not change the essential physics, as will be
 76 discussed in section 3.

77 Following *Denton et al.* [2010] and *Gary et al.* [2010], a subtracted Maxwellian distri-
78 bution is used to initialize the protons in the simulation,

$$79 \quad f_p(\mathbf{v}) = f_1(\mathbf{v}) - f_2(\mathbf{v}), \quad (1)$$

80 with

$$81 \quad f_j(\mathbf{v}) = \frac{n_j}{(\pi v_j^2)^{3/2}} \exp(-v^2/v_j^2). \quad (2)$$

82 Here $v^2 = v_{\parallel}^2 + v_{\perp}^2$, $v_j = \sqrt{2T_j/m_j}$ is the j th species thermal speed (both are protons). This
83 distribution is still isotropic although non-Maxwellian. This simplifies the physics involved
84 by excluding the possible development of the Alfvén cyclotron instability which can be
85 driven by anisotropic protons [*Gary, 1993*]. We choose the dimensionless parameters to
86 be $n_1/n_0 = 6.3$, $n_2/n_0 = 5.3$, $T_1/(m_p v_A^2) = 0.4$, $T_2/T_1 = 0.9$, where n_0 is the background
87 plasma density and v_A is the Alfvén velocity. Note that $n_2/n_1 < (T_2/T_1)^{3/2}$ is required to
88 avoid negative values in $f_p(\mathbf{v})$. With these parameters, $\beta_p = (n_1 T_1 - n_2 T_2)/(B_0^2/2\mu_0) =$
89 $2(n_1 T_1 - n_2 T_2)/(n_0 m_p v_A^2) = 1.2$ and the black line in Figure 1 illustrates the reduced
90 perpendicular velocity distribution

$$91 \quad f_p(v_{\perp}) = \int_{-\infty}^{\infty} dv_{\parallel} \int_0^{2\pi} d\phi f_p(\mathbf{v})$$

$$92 \quad = \frac{2n_1}{v_1^2} \exp(-v^2/v_1^2) - \frac{2n_2}{v_2^2} \exp(-v^2/v_2^2), \quad (3)$$

93 where ϕ is the azimuthal angle of the perpendicular velocity component. The reduced
94 perpendicular velocity distribution has positive $\partial f_p(v_{\perp})/\partial v_{\perp}$ in the range of $0 < v_{\perp} <$
95 $0.5v_A$. Electrons in the simulation have a Maxwellian distribution and $T_e/T_1 = 0.01$.

96 Linear kinetic dispersion theory for electromagnetic fluctuations in a homogeneous,
97 magnetized, collisionless plasma is first applied to the instability analysis. The Cartesian

98 coordinate system of the linear dispersion analysis [Gary, 1993] admits spatial variations
 99 in both the direction parallel to \mathbf{B}_0 (denoted by \parallel) and one direction perpendicular to
 100 the background field (denoted by \perp), but no spatial variations in the other perpendicular
 101 direction (denoted by $\perp\perp$). The \perp , \parallel , and $\perp\perp$ directions correspond to the x , y , and z
 102 directions in the simulations, respectively. So the wavevector is defined as $\mathbf{k} = k_{\perp}\hat{\mathbf{x}} + k_{\parallel}\hat{\mathbf{y}}$
 103 and the complex frequency is $\omega = \omega_r + i\gamma$ where $\gamma > 0$ represents temporal growth of a
 104 fluctuating normal mode of the plasma.

105 For the initial proton distribution shown in Figure 1 and the plasma parameters stated
 106 above, the ion Bernstein instability is found to grow at frequencies near the first two
 107 proton cyclotron harmonics ($\omega \approx \Omega_p, 2\Omega_p$). The growth rates as a function of $k_{\perp}\lambda_i$
 108 and propagation angle θ (with regard to \mathbf{B}_0) for waves near the first and the second
 109 proton cyclotron harmonics are displayed in the left panel and the right panel of Figure
 110 2, respectively. The asterisk in each panel represents the location of the local maximum
 111 growth rate γ_{max} . For waves of $\omega \approx \Omega_p$, $\gamma_{max}/\Omega_p = 0.044$ at $k_{\perp}\lambda_i \approx 4.8$ and $\theta \approx 85.8^\circ$. For
 112 waves of $\omega \approx 2\Omega_p$, $\gamma_{max}/\Omega_p = 0.034$ at $k_{\perp}\lambda_i \approx 9.3$ and $\theta \approx 86.8^\circ$. The solid black contour
 113 line in each panel represents the contour of $\gamma/\Omega_p = 0.03$. The instability can grow over
 114 wide ranges of $k_{\perp}\lambda_i$ and θ with significant growth rates. Linear analysis also shows that
 115 the amplitude relations among electric and magnetic field components of these waves are
 116 $\delta E_{\perp} \gg \delta E_{\perp\perp} \gg \delta E_{\parallel}$ and $\delta B_{\perp\perp} \geq \delta B_{\parallel} \gg \delta B_{\perp}$, but the amplitude relation between $\delta B_{\perp\perp}$
 117 and δB_{\parallel} changes with β_p quite significantly. The compressible component δB_{\parallel} starts to
 118 dominate as β_p increases.

119 Figure 3 displays the time evolution of the energies in different electric and magnetic
 120 field components in the simulation. The instability is weak and saturates at a very low
 121 level so that an exponential growth phase of the energies does not clearly stand out
 122 in Figure 3. The thermal noise level is still relatively high, although the simulation
 123 has 2000 particles per cell, which is limited by the computational resources available.
 124 Nevertheless, the saturation levels shown by Figure 3 are reliable and physical, because
 125 another simulation with 1000 particles per cell gave the same saturation levels. Figure 3
 126 further shows that $\delta E_{\perp} \gg \delta E_{\perp\perp} \gg \delta E_{\parallel}$ and $\delta B_{\perp\perp} \geq \delta B_{\parallel} \gg \delta B_{\perp}$, in agreement with the
 127 linear kinetic analysis results. Note that the dominant electric field component is δE_{\perp} ,
 128 which is mainly the electrostatic contribution, given the nearly perpendicular propagation
 129 of the instability.

130 Figure 4 displays the compressive magnetic fluctuations from the simulation at $t\Omega_p = 60$.
 131 The top panel shows the contour plot of B_y/B_0 , while the bottom panel presents the spatial
 132 power spectrum of $\delta B_y = B_y - B_0$. The two solid black contour lines in the bottom
 133 panel are the same ones in Figure 2 but are now plotted in the $k_{\perp}\lambda_i - k_{\parallel}\lambda_i$ coordinates.
 134 They represent the contours of $\gamma/\Omega_p = 0.03$ given by linear kinetic dispersion theory for
 135 waves near the first two proton cyclotron harmonics. The lower left contour is for the
 136 first harmonic while the upper right contour is for the second harmonic. The regions of
 137 enhanced fluctuations are close to the two contours and reveal the growth of the waves
 138 near the first two proton cyclotron harmonics. This is further confirmed by Figure 5,
 139 which presents the temporal spectrum of δB_y at $x = 4.8\lambda_i$ and $y = 32\lambda_i$ from $t\Omega_p = 50$
 140 to $t\Omega_p = 100$. Spectral peaks at $\omega \approx \Omega_p, 2\Omega_p$ are clear, in agreement with the prediction

141 of linear kinetic theory that the instability is unstable near the first two proton cyclotron
 142 harmonics.

143 Compared with the $\gamma/\Omega_p = 0.03$ contours, the regions of enhanced fluctuations seem to
 144 shift toward small $k_\perp \lambda_i$ slightly. This shift might be due to the nonlinear evolution of the
 145 simulation system. Linear kinetic analysis suggests that the properties of the instability
 146 are very sensitive to the proton distribution. The proton distribution evolves with time
 147 in the simulation due to wave-particle interactions, as shown in Figure 1. The dashed
 148 red line, the green line, and the blue line represent $f_p(v_\perp)$ derived from the simulation at
 149 $t\Omega_p = 0, 60,$ and $100,$ respectively. The positive slope in $f_p(v_\perp)$ is gradually reduced by
 150 the development of the instability.

3. Summary and Discussion

151 The general properties of an ion Bernstein instability driven by a proton velocity dis-
 152 tribution with positive slope in $f_p(v_\perp)$ at $\beta_p \sim 1$ are studied using linear kinetic disper-
 153 sion theory and two-dimensional electromagnetic PIC simulations. The present results
 154 demonstrate that the instability grows at propagation angles nearly perpendicular to $\mathbf{B}_0,$
 155 saturates at a very low level, and yields spectral peaks at frequencies close to the first few
 156 harmonics of the proton cyclotron frequency. These features resemble the observed fast
 157 magnetosonic waves near the geomagnetic equator in the terrestrial magnetosphere.

158 Linear kinetic dispersion analysis for the same initial proton distribution using realistic
 159 proton-to-electron mass ratio ($m_p/m_e = 1836$) and $\omega_p/\Omega_p = 294$ has been reported by
 160 *Gary et al.* [2010]. They found that the ion Bernstein instability grows at frequencies near
 161 the proton cyclotron harmonics up to $\omega \approx 5\Omega_p.$ The maximum growth rate decreases as

162 the harmonic number increases. For waves of $\omega \approx \Omega_p$, $\gamma_{max}/\Omega_p = 0.038$ at $k_{\perp}\lambda_i \approx 4.87$
 163 and $\theta \approx 86.7^{\circ}$. For waves of $\omega \approx 2\Omega_p$, $\gamma_{max}/\Omega_p = 0.036$ at $k_{\perp}\lambda_i \approx 8.73$ and $\theta \approx 87.9^{\circ}$. The
 164 comparison of the linear kinetic analysis results discussed in section 2 with the work of
 165 *Gary et al.* [2010] shows that the reduced proton-to-electron mass ratio and the relatively
 166 small ω_p/Ω_p used in the present study slightly affect the properties of the ion Bernstein
 167 instability, but do not change the essential physics.

168 A simple subtracted Maxwellian distribution is used to construct the positive slope in
 169 $f_p(v_{\perp})$ in the present study because our linear kinetic dispersion code is based on bi-
 170 Maxwellian velocity distributions [*Gary, 1993*]. Since $n_2/n_1 < (T_2/T_1)^{3/2}$ is required in
 171 equation (1) to avoid negative values of $f_p(\mathbf{v})$, only moderately positive slopes in $f_p(v_{\perp})$
 172 can be used. While our results show that the maximum growth rate is near the funda-
 173 mental proton cyclotron harmonic for the given proton distribution, some observations
 174 [*Boardsen et al., 1992*] show spectra which peak at higher harmonics of the proton cy-
 175 clotron frequency and linear theories based upon more strongly unstable distributions
 176 similarly predict maximum growth at higher harmonics [*Gul'elmi et al., 1975; Horne*
 177 *et al., 2000*]. We find that the growth rates of the ion Bernstein instability near different
 178 proton cyclotron harmonics are very sensitive to the proton distributions which drive it.
 179 More linear kinetic analysis and PIC simulations are needed to further understand the
 180 relationship between the ion free energy and the maximum growing modes.

181 In order to study the effect of the excited electromagnetic fluctuations on the thermal
 182 protons, another PIC simulation similar to the one discussed in section 2 but with an
 183 additional component representing thermal protons has been performed. This run shows

184 that the ion Bernstein instability extracts energy from the energetic protons and transfers
185 the energy into the transverse kinetic energy of the thermal protons and the parallel
186 kinetic energy of the background electrons. These results will be described in more detail
187 elsewhere.

188 **Acknowledgments.** This work was performed under the auspices of the U.S. De-
189 partment of Energy (DOE). It was supported primarily by the Defense Threat Reduction
190 Agency under the “Basic Research for Combating Weapons of Mass Destruction (WMD)”
191 Program, project IACRO # 07-4323I, with additional support from the Heliospheric Guest
192 Investigators Program of the National Aeronautics and Space Administration.

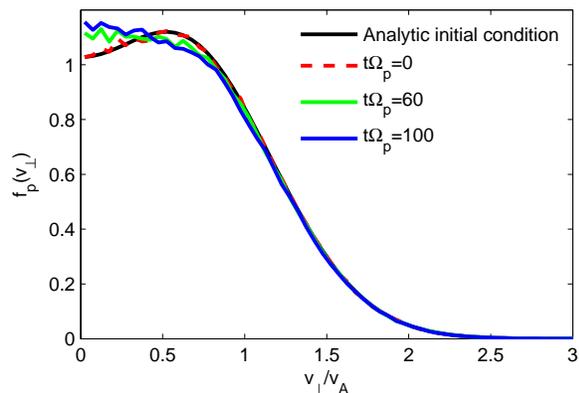

Figure 1. The perpendicular velocity distributions of the protons. The black line displays $f_p(v_\perp)$ of Equation (3), which is used in the linear kinetic dispersion analysis and as an initial condition in the PIC simulations. The dashed red line, the green line, and the blue line represent $f_p(v_\perp)$ derived from the present simulation at $t\Omega_p = 0, 60,$ and $100,$ respectively.

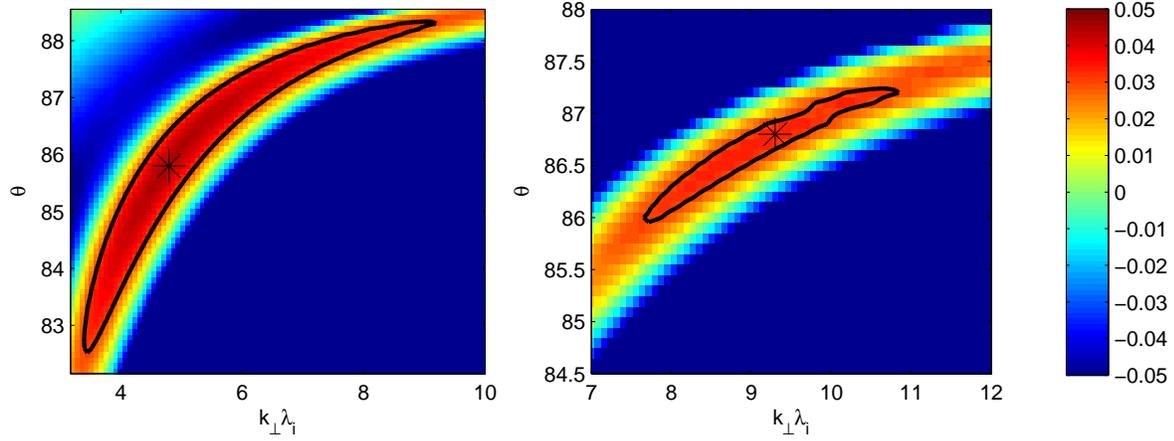

Figure 2. Linear dispersion theory results: Growth rates as a function of $k_{\perp}\lambda_i$ and propagation angle θ (with regard to \mathbf{B}_0) for waves near the first (left panel) and the second (right panel) proton cyclotron harmonics. The asterisk in each panel represents the location of the local maximum growth rate. The solid black contour line in each panel represents the contour of $\gamma/\Omega_p = 0.03$. Note that the minimum value of the color scale corresponds to $\gamma/\Omega_p = -0.05$ so larger damping rates saturate in the plot.

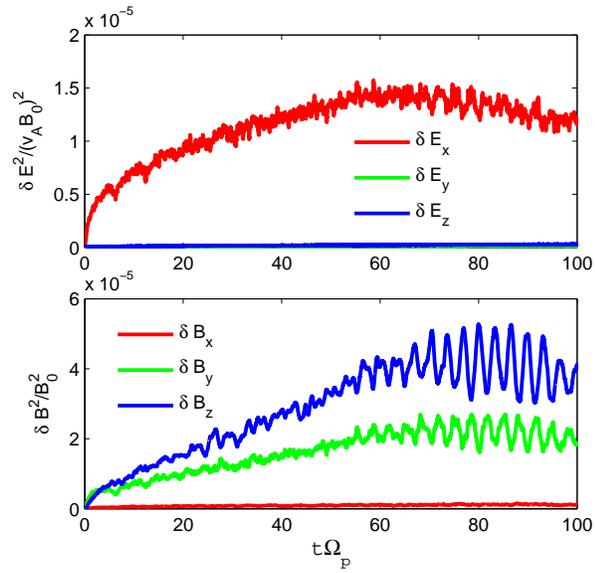

Figure 3. PIC simulation results: The time evolution of the energies in different electric (Top) and magnetic (Bottom) field components.

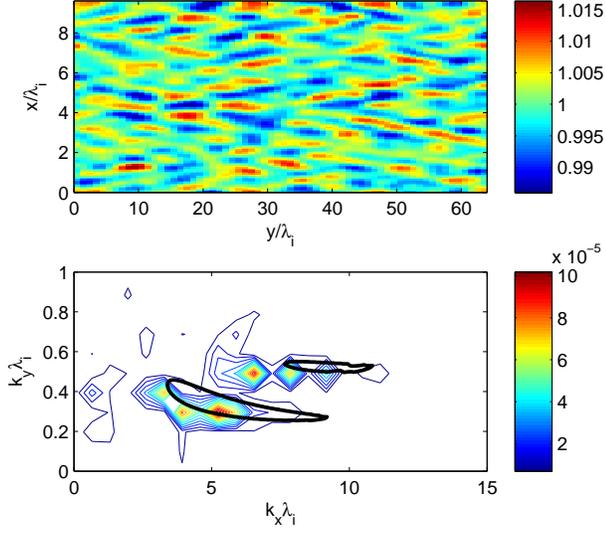

Figure 4. PIC simulation results: The compressive magnetic fluctuations at $t\Omega_p = 60$. Top panel: The contour plot of B_y/B_0 . Bottom panel: The spatial power spectrum of $\delta B_y = B_y - B_0$. The two solid black contour lines in the bottom panel are the same ones in Figure 2 but are now plotted in the $k_\perp \lambda_i$ - $k_\parallel \lambda_i$ coordinates. They represent the contours of $\gamma/\Omega_p = 0.03$ given by linear kinetic dispersion theory for waves near the first two proton cyclotron harmonics. The lower left contour is for the first harmonic while the upper right contour is for the second harmonic.

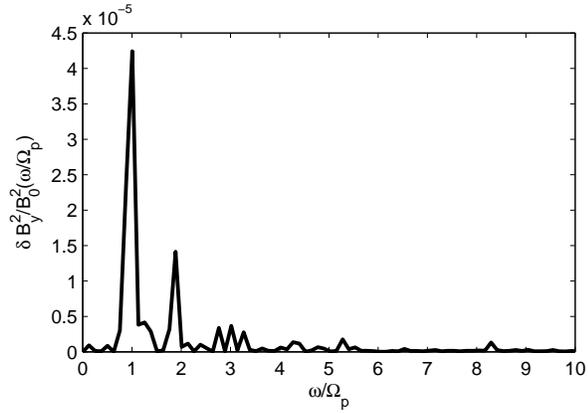

Figure 5. PIC simulation results: The temporal spectrum of δB_y at $x = 4.8\lambda_i$ and $y = 32\lambda_i$ from $t\Omega_p = 50$ to $t\Omega_p = 100$.
