5 **Abstract.** Two-dimensional hybrid (kinetic ions, massless fluid electrons)  
6 simulations of the Kelvin Helmholtz Instability (KHI) for a magnetopause  
7 configuration with a varying density jump and magnetic shear across the bound-  
8 ary are carried out to examine how the transport of magnetosheath plasma  
9 into the magnetosphere is affected by these conditions. Low magnetic shear  
10 conditions where the magnetosheath magnetic field is within  $30^\circ$  of north-  
11 ward is included in the simulations because KHI is thought to be important  
12 for plasma transport only for northward or near-northward interplanetary  
13 magnetic field orientations. The simulations show that coherent vortices can  
14 grow for these near-northward angles, and that they are sometimes more co-  
15 herent than for pure northward conditions because the turbulence which breaks-  
16 down these vortices is reduced when there are magnetic tension forces. With  
17 increasing magnetic shear angle and increasing density jump, the growth rate  
18 is reduced, and the vortices do not grow to as large of size which reduces the  
19 plasma transport. By tracking the individual particle motions diffusion co-  
20 efficients can be obtained for the system, where the diffusion is not classi-  
21 cal in nature but instead has a time dependence resulting from both the in-  
22 creasingly large-scale vortex motion and the small-scale turbulence gener-  
23 ated in the break-down of the instabilities. Results indicate that diffusion  
24 on the order of  $10^9$  m<sup>2</sup>/s could possibly be generated by KHI on the flanks  
25 of the magnetosphere.

## 1. Introduction

26 It is not well understood how the low latitude boundary layer (LLBL) is populated  
27 during northward IMF conditions when reconnection at the dayside magnetopause is  
28 not favored. The primary candidate mechanisms for this plasma entry are thought to  
29 be double high-latitude reconnection, diffusion resulting from plasma waves and drift  
30 instabilities, and the Kelvin-Helmholtz instability [see review in *Scholer and Treumann,*  
31 *1997; Phan et al., 2005*]. Evidence for double high-latitude reconnection has been seen by  
32 spacecraft and ground-based observations [e.g., *Lavraud et al., 2006; Imber et al., 2007;*  
33 *Marcucci et al., 2008*] and analysis of the waves at the magnetopause suggests that they  
34 may be only marginally capable of the necessary diffusivities for populating the LLBL  
35 [e.g., *Scholer and Treumann, 1997*]. The role of Kelvin-Helmholtz instability (KHI) was  
36 initially expected to be minor because KHI was thought to be a surface wave phenomena  
37 that was not widely unstable and was not capable of fast or efficient plasma transport  
38 [e.g., *Axford, 1964*], but recent simulation work and observations indicate that KHI may  
39 be more important than initially thought. This manuscript focuses on the KHI as a  
40 plasma transport mechanism for northward IMF.

41 MHD and Hall-MHD simulations have shown that the instability is indeed unstable  
42 for a range of conditions at the magnetopause and that the instability grows beyond  
43 the surface wave to form rolled-up vortices which can engulf magnetosheath plasmas and  
44 transport them inside the magnetosphere as the vortex breaks down through reconnection  
45 or other process [e.g., *Huba, 1994; Min et al., 1997; Nykyri and Otto, 2001; Nakamura and*  
46 *Fujimoto, 2005; Nykyri and Otto, 2004*]. Spacecraft have themselves seen evidence of

47 KH waves and rolled-up vortices on the flanks of the magnetosphere [e.g., *Ogilvie and*  
48 *Fitzenreiter*, 1989; *Chen et al.*, 1993; *Fairfield et al.*, 2000; *Hasegawa et al.*, 2004, 2006;  
49 *Taylor et al.*, 2008], however observations have not been able to quantify the degree of  
50 plasma mixing that is occurring. In order to better understand how effective KHI may  
51 be at transporting plasma across the boundary, we carry out hybrid simulations with  
52 kinetic ions and massless fluid electrons, so that we may track the individual particle  
53 motions. Although both MHD computations and hybrid simulations well represent the  
54 growth of the instability, only hybrid simulations follow individual particle motions and  
55 permit quantification of the plasma mixing.

56 Some of the first hybrid simulations (kinetic ion, fluid electron) of KHI at the mag-  
57 netopause for northward IMF conditions were carried out by *Terasawa et al.* [1992] and  
58 *Thomas and Winske* [1993]. *Terasawa et al.* [1992] simulated one wavelength of the dom-  
59 inant KH mode for varying velocity shear layer width in a uniform density plasma and  
60 found that plasma mixing occurred on a timescale faster than the roll-up time of the  
61 vortex, which is the mixing time predicted by MHD theory. By calculating the number  
62 of simulation cells containing a mix of magnetosheath and magnetosphere plasmas, they  
63 determined that the plasma mixing increased with a “ $t^2$ ” dependence. As the vortex  
64 grows, the individual particles become efficiently mixed within the vortex structure over  
65 spatial scales larger than a Larmor radius, which is the mixing layer thickness predicted  
66 by MHD theory. *Thomas and Winske* [1993] used a larger simulation box to model the  
67 growth of several vortices and found that in this case the mixing does not follow a  $t^2$   
68 dependence but instead shows a more linear temporal dependence. When the simulation  
69 box is large enough to allow are multiple vortices, they coalesce together to form even

70 larger vortices until there is one final vortex of the size of the simulation box. Yet even  
71 though the plasma mixing did not follow a  $t^2$  dependence, it was still fast because the  
72 coalescence of vortices enhanced the plasma mixing, a result also found by *Fujimoto and*  
73 *Terasawa* [1994] and *Fujimoto and Terasawa* [1995]. *Fujimoto and Terasawa* [1995] found  
74 that the plasma mixing was reduced, however, for increasing relative density (and relative  
75 magnetic field strength) between the magnetosheath and magnetosphere.

76 Recently, ideal MHD and full-particle simulations carried out by *Matsumoto and*  
77 *Hoshino* [2004] and *Matsumoto and Hoshino* [2006] showed that the KH vortices are  
78 rapidly broken down by the growth of secondary KH and Rayleigh Taylor (RT) instabili-  
79 ties within the vortex structure. This break-down causes strong turbulence in the system,  
80 and plasma mixing subsequently increases. In our recent hybrid simulation results [*Cowee*  
81 *et al.*, 2009, hereafter referred to as paper 1], we also found this effect to be particularly  
82 important in enhancing plasma transport from KHI. Transport by KHI also occurs as a  
83 result of reconnection of strongly twisted magnetic fields in KHI vortices even when the  
84 IMF is nearly northward [*Nykyri and Otto*, 2001, 2004]; however, as we show later this  
85 process does not occur in our simulations.

86 *Miura* [1995] carried out the first MHD simulations of KHI which included a magnetic  
87 shear across the magnetopause. He found that northward IMF (i.e. no magnetic shear)  
88 was the most unstable condition, and the growth rate decreased for off-northward angles.  
89 For southward IMF the growth rate was positive but the magnetopause only undulated  
90 and did not form recognizable KH waves or vortices due to the magnetic tension forces.  
91 Since then, more MHD simulations of KHI have included magnetic shear angles within

92 30° of northward [*Takagi et al.*, 2006; *Keller and Lysak*, 1999], but kinetic simulations  
93 have not yet considered this condition.

94 KH vortices have been identified in spacecraft observations from their particular periodic  
95 signatures in flow velocity, magnetic field, density, and temperature. For example, in the  
96 *Hasegawa et al.* [2004] report on Cluster observations of the KH-unstable magnetopause  
97 during northward IMF conditions, the plasma flow vectors exhibited an anti-clockwise  
98 rotation around the vortex center as is expected for the instability at the dusk side of the  
99 magnetopause. Correlated with the flow vectors were periodic variations in density and  
100 temperature associated with the high density, cold solar wind and the low density, hot  
101 magnetospheric plasma. Additionally, both cold solar wind and hot magnetospheric ions  
102 were found to co-exist in the same regions on the magnetospheric side of the magnetopause.  
103 The magnetic field variations in the high and low density regions were found to have the  
104 correct polarity for KH vortices (based on MHD simulations). *Hasegawa et al.* [2004]  
105 concluded that this was a rolled-up vortex in which plasma mixing was occurring, but  
106 since they did not find the magnetic stresses or D-shaped ion distributions associated with  
107 reconnection, they did not believe that process was playing a role in the plasma mixing.  
108 Other observations of KH vortices, however, have found evidence for reconnection within  
109 the vortices [*Nykyri et al.*, 2006; *Nishino et al.*, 2007].

110 Rolled-up vortices have also been identified using the single-spacecraft method proposed  
111 by *Hasegawa et al.* [2006]. This technique, based on the MHD simulations of *Takagi et al.*  
112 [2006], looks for the low density fast tailward flows produced by the vortex motion. Such  
113 flows occur within a rolled-up KH vortex because the low density solar wind plasma  
114 must rotate faster than the high density magnetospheric plasma so that force balance is

115 maintained in the radial direction. Using Cluster and Geotail data, *Hasegawa et al.* [2006]  
116 showed that the lowest density flows associated with KH vortices had tailward velocities  
117 greater than their initial magnetosheath velocities. Similar results from Double Star data  
118 were found by *Taylor et al.* [2008] during which evidence for phase space plasma mixing  
119 was found in the ion data [*Taylor and Lavraud*, 2008].

120 Paper 1 describes two-dimensional hybrid simulations of the KHI carried out for condi-  
121 tions with uniform magnetic field across the simulation box (i.e. no magnetic shear across  
122 magnetopause) perpendicular to the shear flow velocity (most unstable configuration)  
123 with a density jump between the magnetosheath and magnetosphere up to a factor 10.  
124 In this manuscript we continue the work described in paper 1 but we include a magnetic  
125 shear across the boundary and increase the shear velocity jump, to include more realistic  
126 conditions. The paper is organized as follows: section 2 describes the methods used in  
127 the paper; section 3 describes the simulation results which include the simulated growth  
128 of vortices (section 3.1), what a hypothetical spacecraft would see if it flew through the  
129 center of the simulation box (section 3.2), and the diffusion of magnetosheath plasma into  
130 the magnetosphere (section 3.3); section 4 summarizes the results.

## 2. Methodology

131 For our KH-unstable magnetopause configuration, the boundary sits in the middle of  
132 the simulation box with the magnetosheath plasma on the left ( $-x$ ) and the magne-  
133 tosphere plasma on the right ( $+x$ ). The conditions in the magnetosheath (“s”) are  $n_s = 5$   
134 protons/cc,  $B_s = 20$  nT, and  $T_{is} = T_{es} = 10$  eV ( $\beta = 0.05$ ,  $\rho_L = 23$  km). The condi-  
135 tions in the magnetosphere (“m”) are varied depending on the density jump across the  
136 magnetopause boundary: equal to 1/4, or 1/10 the density in the magnetosheath. For

137 uniform density, the magnetosphere conditions are  $n_m = 5$  protons/cc,  $B_m = 20$  nT, and  
 138  $T_{im} = T_{em} = 10$  eV ( $\beta = 0.05$ ,  $\rho_L = 23$  km). For a density jump of 4, the magnetosphere  
 139 conditions are  $n_m = 1.25$  protons/cc,  $B_m = 20$  nT,  $T_{im} = T_{em} = 40$  eV ( $\beta = 0.05$ ,  $\rho_L = 46$   
 140 km). For a density jump of 10, the magnetosphere conditions are  $n_m = 0.5$  protons/cc,  
 141  $B_m = 20$  nT,  $T_{im} = T_{em} = 100$  eV ( $\beta = 0.05$ ,  $\rho_L = 72$  km). On the magnetosphere side,  
 142 the magnetic field points northward ( $+z$ ), while on the magnetosheath side, it points at  
 143 an angle  $\theta_s = 0^\circ$ ,  $15^\circ$ , or  $30^\circ$  away from northward in the  $y$ - $z$  plane. The velocity shear  
 144 jump,  $V_s$ , is equal to  $1 v_A$  calculated on the high density side ( $v_A = 195$  km/s), and the  
 145 shear layer half-thickness,  $a$ , is  $1 c/\omega_{pi}$  calculated on the high density side ( $c/\omega_{pi} = 102$   
 146 km). These conditions are meant to be generally representative of the KH-unstable mag-  
 147 netopause conditions and not specifically to any particular spacecraft observations. We  
 148 start with thin shear layers and let small vortices grow and coalesce in time to larger  
 149 structures.

150 In this study we use a two-dimensional hybrid code, the basic equations of which are  
 151 given in Appendix A. In the calculations we assume a small, constant resistivity ( $\eta =$   
 152  $10^{-4}$ ) and a scalar electron pressure. With such a model, it has been previously shown  
 153 that magnetic reconnection does not occur unless either a model for the electron pressure  
 154 tensor [*Hesse et al.*, 1995] or an enhanced localized resistivity [*Kuznetsova et al.*, 1996] is  
 155 added to break the frozen-in condition in the electric field equation (A8).

156 The system size is  $120 c/\omega_{pi}$  with 512 grid cells in  $x$  direction and  $120 c/\omega_{pi}$  with 512  
 157 grid cells in the  $y$  direction, where  $x$  is normal to the initial magnetopause boundary and  
 158  $y$  is parallel to it. The boundary conditions are periodic in the  $y$  direction and reflective  
 159 in the  $x$  direction. We chose this simulation box size so that multiple wavelengths of the

160 dominant mode could grow and the interaction can proceed for a long time (i.e.,  $\Omega_i t \sim 600$ )  
 161 before the reflective boundaries became an issue. All simulations use 100 superparticles  
 162 per cell and a timestep of  $0.05\Omega_i^{-1}$ .

### 3. Results and Discussion

#### 3.1. Vortex Formation

163 We carried out a set of nine simulations for each of the combinations of density jump  
 164  $n_s/n_m = 1, 4,$  and  $10$  and magnetic shear angle  $\theta_s = 0^\circ, 15^\circ,$  and  $30^\circ$ . Figures 1-3  
 165 show the magnetosheath densities in the nine simulations at  $\Omega_i t = 150$  and  $600$ . Figure  
 166 1, which shows the uniform density simulations, shows that the KHI is unstable for all  
 167 magnetic shear angles tested, growing from small fluctuations (Figure 1 top panels) to  
 168 rolled-up vortices which coalesce to eventually form one large vortex structure limited by  
 169 the simulation box size (Figure 1 bottom panels). The size of the initial vortices are  $\sim 15$ -  
 170  $20 c/\omega_{pi}$  consistent with the linear theory prediction that the wavenumber of maximum  
 171 growth,  $k$ , is  $ka \sim 0.4$  [*Miura and Pritchett, 1982*]. It is interesting that the structure of  
 172 the large vortex at  $\Omega_i t = 600$  for the  $\theta_s = 0^\circ$  and  $\theta_s = 15^\circ$  simulations appears equally  
 173 large and rolled-up, yet it is much more coherent in the simulation with the magnetic  
 174 shear. With an increase in shear angle, the growth rate decreases [*Miura, 1995*], but  
 175 there is little effect here on the size of the vortex. The reduced growth is evident in the  
 176 simulation with  $\theta_s = 30^\circ$  in that vortex structure is not as large or as rolled-up as in the  
 177 other simulations. The apparent reduction in short-wavelength turbulence in the  $\theta_s = 15^\circ$   
 178 and  $30^\circ$  simulations is an interesting effect which will be discussed later.

179 Figure 2, which shows the  $n_s/n_m = 4$  simulations, shows that the KHI is again unstable  
 180 for all magnetic shear angles tested. The fluctuations begin small and coalesce, but the

181 vortices are eroded by secondary KH and RT instabilities [*Matsumoto and Hoshino, 2004*],  
 182 forming long and narrow filamentary structures which can break off and contribute to the  
 183 turbulent system. At  $\theta_s = 0^\circ$ , the system is very turbulent at  $\Omega_i t = 600$  compared to  
 184 that at  $\theta_s = 15^\circ$  or  $\theta_s = 30^\circ$  which show a more coherent KH structure. The structures  
 185 at  $\theta_s = 15^\circ$  and  $\theta_s = 30^\circ$  appear more wave-like than vortex-like in comparison to the  
 186 nicely rolled-up structures in Figure 1, but they do still contain plasma on vortical paths  
 187 within the structures. The secondary instabilities are active, and are eroding the high-  
 188 density (magnetosheath plasma) vortex arm as it rolls into the low-density (magnetosphere  
 189 plasma) region.

190 Figure 3, which shows the  $n_s/n_m = 10$  simulations, shows that the KHI grows for the  
 191 magnetic shear simulations with  $\theta_s = 0^\circ$  and  $15^\circ$ . At  $\theta_s = 30^\circ$ , the magnetic tension forces  
 192 are too high for this non-uniform density simulation to show even a slight undulation of  
 193 the boundary. We see again that the KH structure at  $\Omega_i t = 600$  is more coherent at  
 194  $\theta_s = 15^\circ$  than  $\theta_s = 0^\circ$ , and there is much less turbulence present. The KH structure is  
 195 wave-like as the vortex structure is eroded by secondary instabilities.

196 An interesting result here is that the simulations with low magnetic shear show a more  
 197 coherent KH structure at later times than do the simulations for purely northward IMF. In  
 198 the pure northward case, there is more small-scale turbulence which acts to break-down  
 199 the vortex structures over time. The effect is particularly enhanced when the density  
 200 jump between the magnetosheath and magnetosphere is increased because the growth  
 201 of secondary instabilities is enhanced. With the introduction of magnetic shear there is  
 202 a magnetic tension force from the nonzero  $B_y$  which prevents a more turbulent system  
 203 from forming. In the non-uniform density simulations, the vortex structure is no longer

204 rapidly broken down by the turbulence as the growth rates of the secondary instabilities  
205 are reduced [Matsumoto and Hoshino, 2004]. Small-scale turbulence which disrupts the  
206 vortex structure is also seen, as has been found in Hall-MHD simulations of KHI when  
207 there is a density jump [Huba, 1994; Nykyri and Otto, 2004]. Comparison of hybrid and  
208 fluid simulations for the Rayleigh-Taylor instability on ion gyroradius scales shows that  
209 short wavelength fluctuations are better defined in fluid calculations while particle noise  
210 in hybrid calculations tends to obscure small-scale features [Huba and Winske, 1998]. To  
211 verify that it is the presence of magnetic shear and not just the reduced growth rate of  
212 the primary KH-unstable mode which yielded a less turbulent system, we ran simulations  
213 with an increased velocity shear up to  $2 v_A$  (not shown). With the larger growth rate  
214 from the larger velocity shear, larger vortex structures were generated for the  $\theta_s = 15^\circ$   
215 and  $\theta_s = 30^\circ$  simulations, but they did not show the turbulent break-down exhibited in  
216 the  $\theta_s = 0^\circ$  simulations. Additionally, at these higher shear velocities, the  $n_s/n_m = 10$   
217 simulation with  $\theta_s = 30^\circ$  can generate KH waves (not shown).

### 3.2. Hypothetical Spacecraft Observations

218 The coherent structure of the nonuniform density simulations with magnetic shear could  
219 explain why observations such as those discussed in the Introduction demonstrate clearly  
220 periodic structure at the magnetopause which is being attributed to the KHI. If the vortex  
221 structure were always rapidly broken down by turbulence then it would be very difficult  
222 to identify and would not exhibit a regular periodicity. Figures 4 - 6 show simulated  
223 quantities in the grid cells along the  $y$  direction in the middle of the simulation box at  
224  $\Omega_i t = 150$  for the s with  $n_s/n_m = 1, 4$  and  $10$  with  $\theta_s = 15^\circ$ . Periodic structure is  
225 particularly evident in the uniform density simulation, becoming less regular with the

226  $n_s/n_m = 4$  simulation, and irregular with the  $n_s/n_m = 10$  simulation, though it still  
 227 exhibits the weak signatures of vortex motion in the fluctuating magnetic field and bulk  
 228 velocity.

229 For the uniform density simulations, the periodic structure for the  $\theta_s = 0^\circ$  simulation  
 230 at  $\Omega_i t = 150$  (not shown) is very similar to that shown in Figure 4; compared to the  
 231  $\theta_s = 30^\circ$  simulation at  $\Omega_i t = 150$  (not shown), the structure is again regularly periodic,  
 232 but the velocity and magnetic field perturbations are much smaller in the  $x$  direction. For  
 233 the  $n_s/n_m = 4$  simulations, the periodic structure for the  $\theta_s = 0^\circ$  simulation at  $\Omega_i t = 150$   
 234 (not shown) is less regularly periodic than that shown in Figure 5, which is not surprising  
 235 given the enhanced turbulence in the former simulation. In the  $\theta_s = 30^\circ$  simulation at  
 236  $\Omega_i t = 150$  KHI is not well developed so we consider the simulated quantities at  $\Omega_i t = 300$   
 237 instead (not shown), which show an irregular periodic structure with weak signatures of  
 238 vortex motion. For the  $n_s/n_m = 10$  simulations, the periodic structure for the  $\theta_s = 0^\circ$   
 239 simulation at  $\Omega_i t = 150$  (not shown) is irregular just as in Figure 6, though signatures of  
 240 vortex motion can be identified.

241 The periodic structure exhibits signatures in agreement with the observations, showing  
 242 alternating periods of high density, low temperature plasma (magnetosheath) and low  
 243 density, high temperature plasma (magnetosphere) correlated with the perturbations in  
 244 the magnetic field and bulk plasma flow. From the temperature variations, we see that  
 245 plasma from the two sides is simply being mixed and is not being heating by the instability.

246 We also find that the vortices show the low-density fast tailward flows that *Hasegawa*  
 247 *et al.* [2006] indicate as a means of identifying rolled-up vortices from single-spacecraft  
 248 observations. As shown in figure 7, these structures are more defined for  $\theta_s = 0^\circ$  (light

249 gray) than at  $\theta_s = 15^\circ$  (dark gray), in agreement with the MHD simulations of *Takagi*  
 250 *et al.* [2006]. As the shear angle is increased, the low density flows are not accelerated to  
 251 as high of tailward velocity as when there is no magnetic shear. Indeed for the  $\theta = 30^\circ$   
 252 cases, low-density flows faster than the initial shear velocity jump are not generated at  
 253 all and so are not shown in the figure. Yet the lack of observed low-density, high tailward  
 254 flows associated with KH vortices [i.e., *Lavraud et al.*, 2009] does not conclusively prove  
 255 that a vortex is not rolled-up or that plasma mixing is not occurring. Since the flows are  
 256 formed because of a difference in plasma density across the magnetopause, the uniform  
 257 density simulations do not generate them even though the vortices are clearly rolled-up  
 258 (see Figure 1). If the density jump is more than 1 but less than 4 it is also possible  
 259 that such flows might not be generated, although we have not tested this hypothesis. We  
 260 note also that these low-density fast tailward flows were obtained in our simulation for  
 261 vortex structures which rolled up and yielded significant plasma mixing (see next section)  
 262 through means other than reconnection.

### 3.3. Plasma Transport

263 To examine plasma transport we calculate the diffusion coefficients in the manner of  
 264 paper 1. We consider a fundamental treatment of diffusion which involves tracking the  
 265 particle motion in the direction normal to the magnetopause and then finding the mean  
 266 square displacement of the particles,  $\langle \Delta x^2 \rangle$ , over time. The diffusion coefficient,  $S$ , is  
 267 then defined as

$$S = \langle \Delta x^2 \rangle / t . \quad (1)$$

268 Note that since  $B_0$  is northward on the magnetosphere side, the direction perpendicular  
 269 to the magnetopause boundary is also perpendicular to  $B_0$ . On the magnetosheath side,  
 270 diffusion in the plane perpendicular to  $B_0$  would involve calculation in a spatial  $z$  direction  
 271 that does not exist in our two-dimensional simulation. We therefore consider  $S$  to relate  
 272 to the direction strictly perpendicular to the magnetopause. For this calculation, we track  
 273 particles in the region  $15 c/\omega_{pi} < x < 105 c/\omega_{pi}$  which includes the interaction region but  
 274 is away from the reflective boundaries.

275 Figure 8 shows the calculated mean-square displacement since  $\Omega_i t = 0$  and the corre-  
 276 sponding diffusion coefficients at several times during the various simulations. As was  
 277 demonstrated in paper 1, the diffusion coefficients increase in magnitude over time, re-  
 278 sembling what [Treumann, 1997] referred to as “super-diffusion”. This is certainly not  
 279 diffusion in the classical sense, as the motion of particles and their transport perpendicu-  
 280 lar to the magnetopause is a function not only of the small-scale turbulence generated by  
 281 the instabilities but also the large-scale vortex motion. The inseparability of these large  
 282 and small-scale dynamic effects necessitates that the diffusion coefficient include both.  
 283 We refer to our diffusion coefficient as  $S$  rather than  $D$  to avoid misinterpretation of the  
 284 result as a typical diffusion coefficient that is time-independent.

285 For the uniform density simulations, the  $\theta_s = 15^\circ$  simulation shows a larger  $\langle \Delta x^2 \rangle$   
 286 than the  $\theta_s = 0^\circ$  simulation because the final vortex in the  $\theta_s = 15^\circ$  simulation forms  
 287 a more coherent large-scale structure; the  $\theta_s = 30^\circ$  simulation exhibits a much smaller  
 288 diffusion coefficient because the size of the instability is reduced. For the non-uniform  
 289 density simulations,  $\langle \Delta x^2 \rangle$  is largest for  $\theta_s = 0^\circ$  where there is the most small-scale  
 290 turbulence. As the magnetic shear angle is increased  $\langle \Delta x^2 \rangle$  over time is also reduced. In

291 these simulations, where enhanced turbulence from the secondary instabilities is possible,  
292 the more coherent vortex structures for low magnetic shear angles are not as important in  
293 enhancing particle transport as the turbulent break-down of the vortices. We note that by  
294  $\Omega_i t = 600$ , the diffusion coefficients for some of the simulations do appear to be leveling  
295 out, which is likely the result of the interaction region in these simulations reaching the  
296 edges of the simulation box.

297 Diffusion coefficients have been estimated in previous hybrid simulation work by *Tera-*  
298 *sawa et al.* [1992], *Fujimoto and Terasawa* [1994] and *Thomas and Winske* [1993] by  
299 finding analytic solutions to an assumed diffusion equation for the system and then solv-  
300 ing them using the various derived mixing quantities obtained at late times during the  
301 simulation. Because these studies all assumed that diffusion of plasma by KHI is ef-  
302 fectively described by a diffusion coefficient which is independent of time, we need to  
303 compare their diffusion coefficients with our diffusion coefficients obtained at particular  
304 times during the simulations. In the simulations of *Terasawa et al.* [1992] and *Fujimoto*  
305 *and Terasawa* [1994], they each carried out a simulation with velocity shear jump and  
306 shear layer half-width similar to ours, however they used a much smaller simulation box.  
307 Because the KHI vortices will ultimately grow to fill the simulation box, the box size  
308 is fundamental limiting parameter on the plasma transport. In the small-box case, the  
309 mixing reaches an asymptotic value over time as the single vortex completely fills the  
310 simulation box, is confined by the boundaries, and eventually fully mixes the plasma  
311 within the box. Thus we expect their diffusion coefficients to generally agree with ours  
312 at times up until the vortices have grown to the size of their simulation boxes. After this  
313 time, the vortices in our larger simulation box can continue to grow and we can obtain

314 larger diffusion coefficients than they did. In the simulations carried out by *Thomas and*  
 315 *Winske* [1993], they used a larger simulation box, but considered a smaller velocity shear  
 316 jump and shear layer half-width than we did. Thus we expect their diffusion coefficients  
 317 should be smaller than ours, because their instability has a lower growth rate and smaller  
 318 wavelength KH mode at maximum growth.

319 *Terasawa et al.* [1992] assumed a constant diffusion coefficient from a fit to the area  
 320 covered by “mixed” simulation cells (i.e. cells with at least a quarter of their density  
 321 from each of magnetosheath and magnetosphere particles) over time, and determined  
 322  $D = 0.21, 0.33$  and  $0.49(c/\omega_{pi})^2\Omega_i$  for simulations with  $a = 1, 1.5,$  and  $2 c/\omega_{pi}$ . In terms  
 323 of comparison to our normalized diffusion coefficients, note that since  $a$  is equal to  $1 c/\omega_{pi}$   
 324 the values in the Figure 8 can be thought of as normalized to the ion inertial length instead  
 325 of the velocity shear layer half-width. In this case, the diffusion coefficient from *Terasawa*  
 326 *et al.* [1992] for a uniform density simulation with  $\theta_s = 0^\circ$ , shear layer half-width of  $1 c/\omega_{pi}$   
 327 and velocity shear jump of  $1 v_A$  is in agreement with our simulation results obtained around  
 328  $\Omega_i t = 300$ . They obtained their diffusion coefficient from a fit to their simulated mixing  
 329 at  $\Omega_i t > 200$ , when the single dominant mode vortex they were simulating had filled the  
 330 simulation box and the mixing area had reached an asymptotic state. Similarly, *Fujimoto*  
 331 *and Terasawa* [1994] used the area of the mixing layer calculated from the number of  
 332 mixed simulation cells at late times during the simulation run to get a diffusion coefficient  
 333 of  $D = 0.24(c/\omega_{pi})^2\Omega_i$ . This value from their uniform density simulation with  $\theta_s = 0^\circ$ ,  
 334 shear layer half-width of  $2 c/\omega_{pi}$  and shear velocity jump of  $1 v_A$  is also within the range  
 335 we simulated for times just after  $\Omega_i t = 300$ .

336 *Thomas and Winske* [1993] determined diffusion coefficients from the rate of change of  
337 the mixing layer width,  $\delta Z$ , which was a proportional to the number of particles crossing  
338 the midplane of the simulation over time. They determined the value of  $D$  to be at most  
339  $0.03V_D a$  where  $V_D$  is the velocity shear jump ( $V_s$  in our simulations). Translated into units  
340 normalized by the ion inertial length and gyrofrequency,  $D \simeq 0.007(c/\omega_{pi})^2\Omega_i$ . This value  
341 from their uniform density simulation with  $\theta_s = 0^\circ$ , shear layer half-width of  $0.75 c/\omega_{pi}$   
342 and velocity shear jump of  $0.33 v_A$  is low compared to our diffusion coefficients probably  
343 because of the smaller size and growth rate of the instability and as well as the differences  
344 in the techniques employed to compute the diffusion coefficients.

345 *Fujimoto and Terasawa* [1995] also carried out simulations of KHI growth for a range  
346 of non-uniform densities across the magnetopause and velocity shear layer half-widths.  
347 They found that the plasma mixing was reduced when the density jump across the mag-  
348 netopause was increased, in agreement with our results, but they did not calculate diffusion  
349 coefficients for the various cases so we cannot provide a comparison.

350 From these results, we can consider the important issue of whether or not KHI could  
351 be a dominant mechanism in the transport of solar wind plasma into the magnetosphere  
352 for northward IMF conditions. Because of the magnetospheric magnetic field orientation  
353 and the draping of the solar wind magnetic field, reconnection would be expected to  
354 be the dominant LLBL population mechanism for conditions except those of northward  
355 IMF [*Scholer and Treumann*, 1997]. The canonical diffusivity required for populating  
356 the LLBL is  $10^9 \text{ m}^2/\text{s}$  [*Sonnerup*, 1980] which may or may not be achievable through  
357 viscous processes on the flanks. The focus has been on plasma waves and drift instabilities  
358 driven by density gradients scattering particles in the transition layer, however diffusivities

359 calculated from only the very highest observed wave amplitudes come close to being large  
 360 enough [e.g., *Treumann et al.*, 1991; *Vaivads et al.*, 2004].

361 To compare our normalized simulation results to real-world values, we convert the dif-  
 362 fusion coefficients in Figure 8 using shear layer half width  $a = 102$  km and gyrofrequency  
 363  $\Omega_i = 0.3047$  Hz. We calculate that a diffusion coefficient of  $10^8$  m<sup>2</sup>/s is equivalent to  
 364  $S = 0.03a^2\Omega_i$  (dotted line) and  $10^9$  m<sup>2</sup>/s is equivalent to  $S = 0.32a^2\Omega_i$  (dot-dash line).  
 365 Values greater than  $10^9$  m<sup>2</sup>/s are obtained during the simulations for  $n_s/n_m = 1$  with  
 366  $\theta_s = 0^\circ$  and  $\theta_s = 15^\circ$  between  $\Omega_i t = 350 - 400$  and the simulation with  $n_s/n_m = 4$  with  
 367  $\theta_s = 0^\circ$  around  $\Omega_i t = 450$ . This suggests that plasma transport of the order necessary  
 368 to populate the LLBL could be achieved under certain conditions via KHI; however, we  
 369 reiterate that our diffusion coefficients are time-dependent and should not be used as  
 370 if they were classical diffusion coefficients. This result is not without caveats, namely  
 371 that our system is not a true representation of the global picture. Our simulation is not  
 372 fully three-dimensional and we do not include truly realistic magnetopause conditions in  
 373 a large non-periodic-boundary system stretching from nose to tail. Also importantly, our  
 374 simulation does not model electrons kinetically which is important in truly quantifying  
 375 the plasma transport and in modeling reconnection on fundamental scales. Additionally,  
 376 we do not model inhomogeneities in the magnetosphere such as plasma gradients from  
 377 the plasma sheet and lobes which would ultimately limit the sizes of the vortices. Nev-  
 378 ertheless, it is an interesting result that we can generate local, time-dependent diffusion  
 379 coefficients of the order  $10^9$  m<sup>2</sup>/s in our simple system.

#### 4. Summary

380 We have carried out two-dimensional hybrid simulations (kinetic ions, massless fluid  
381 electrons) of the KHI for different density jumps and near-northward magnetic shear  
382 angles across the magnetopause, starting with a relatively thin shear layer ( $\sim 200$  km).  
383 For no magnetic shear, the uniform density simulation generates large coherent vortices  
384 while in the non-uniform density simulations the coherent vortices are broken down by  
385 secondary KH and RT instabilities yielding a more turbulent system. For a magnetic  
386 shear angle of  $\theta_s = 15^\circ$ , the simulations all show a more coherent vortex structure, as  
387 the turbulence which previously broke-down the instabilities is reduced. For  $\theta_s = 30^\circ$ ,  
388 the magnetic tension force stabilizes the  $n_s/n_m = 10$  simulation so it does not generate  
389 KH waves, but the  $n_s/n_m = 4$  and 1 simulations do. If the shear velocity jump across  
390 the magnetopause is increased then the growth rate of the instability increases and a  
391  $n_s/n_m = 10$  simulation can generate waves.

392 Simulation results show periodic structure in density, temperature, bulk velocity and  
393 magnetic field in general agreement with spacecraft observations. Periods of low and high  
394 density are correlated with period of high and low temperature, as expected for mixing of  
395 cold solar wind and hot magnetosphere plasmas in a vortex structure. Also in agreement  
396 with observations is the generation of low-density fast tailward flows in the rolled-up  
397 vortices for the non-uniform density simulations.

398 To examine diffusive plasma transport by KHI, we considered the fundamental defini-  
399 tion of diffusion and calculated the mean-squared displacement of particles,  $\langle \Delta x^2 \rangle$ ,  
400 over time. Results showed that the  $\langle \Delta x^2 \rangle$  increased nonlinearly with time, and was  
401 higher for the uniform density simulations than the non-uniform density simulations and  
402 decreased with increasing magnetic shear angle. This non-linear increase in the diffu-

403 sion coefficient ( $S = \langle \Delta x^2 \rangle / t$ ) implies enhanced diffusion which is more appropriately  
 404 considered as “super-diffusion” than classical diffusion [*Cowee et al.*, 2009; *Treumann*,  
 405 1997]. It results from the combined effects of large-scale vortex motion and small-scale  
 406 turbulence generated in the break-down of the vortices.

407 The efficiency of KHI in transporting magnetosheath plasma into the magnetosphere  
 408 and populating the LLBL is not well understood, but our results suggest that it could be  
 409 a more important mechanism than previously thought. The canonical diffusivity required  
 410 to populate the LLBL is  $10^9 \text{ m}^2/\text{s}$  [*Sonnerup*, 1980]. Transport of this magnitude due to  
 411 reconnection of twisted fields from the KHI has been measured in the Hall-MHD simu-  
 412 lations [*Nykyri and Otto*, 2004] and we find that such diffusivities of this magnitude are  
 413 obtained in several of our simulations. In the uniform density simulations with  $\theta_s = 0^\circ$  and  
 414  $15^\circ$  and in the  $n_s/n_m = 4$  simulation with  $\theta_s = 0^\circ$ , the time-dependent diffusion coefficient  
 415 around  $\Omega_i t = 400$  (when the smaller vortices that great out of a thin shear layer have  
 416 coalesced into one or two large vortices in the simulation box) reached values equivalent  
 417 to  $10^9 \text{ m}^2/\text{s}$ . This result should be treated carefully, since our diffusion coefficients are  
 418 not classical diffusion coefficients but are instead time-dependent. Additionally, we note  
 419 that the higher diffusivities yielded by the smaller density jump simulations could suggest  
 420 that double high-latitude reconnection, which acts to increase the plasma density in the  
 421 magnetosphere, plays a role in the growth of KHI [*Bouhram et al.*, 2005; *Hasegawa et al.*,  
 422 2009] and therefore helps facilitate this enhanced plasma transport.

## Appendix A: Hybrid Model Equations

423 The two-dimensional hybrid simulation code treats ions kinetically using standard  
 424 particle-in-cell techniques and treats electrons as a massless, charge neutralizing fluid.

425 Velocities and electromagnetic fields are maintained in all three directions, while parti-  
 426 cle position is determined in two dimensions. A leapfrog scheme is used to advance the  
 427 particle positions and velocities in time.

428 The particle motion is described by the equations of motion:

$$m_i \frac{d\mathbf{v}_p}{dt} = q_i \left( \mathbf{E} + \frac{\mathbf{v}_p \times \mathbf{B}}{c} \right) - e\eta \mathbf{J}, \quad (\text{A1})$$

$$\frac{d\mathbf{x}_p}{dt} = \mathbf{v}_p, \quad (\text{A2})$$

429 where  $m_i$  is the ion species mass,  $q_i$  is the ion species charge,  $\mathbf{v}_p$  is the particle's velocity,  
 430  $\mathbf{x}_p$  is the particle's position. The term  $e\eta \mathbf{J}$  is a resistivity term where  $e$  is the proton  
 431 charge,  $\eta$  is the resistivity, and  $\mathbf{J}$  is the current. The electromagnetic fields  $\mathbf{E}$  and  $\mathbf{B}$  are  
 432 determined on the spatial grid and interpolated to the position of the particle. From this  
 433 the ion species number density ( $n_i$ ), charge density ( $q_i n_i$ ), flow velocity ( $\mathbf{V}_i$ ), and current  
 434 ( $\mathbf{J}_i$ ) can also be specified on the grid for each species and then collected for all species to  
 435 determine the total ion density and current.

Electrons are treated as a massless fluid ( $m_e = 0$ ) so the electron momentum equation becomes

$$n_e m_e \frac{d\mathbf{V}_e}{dt} = 0 = -en_e \left( \mathbf{E} + \frac{\mathbf{V}_e \times \mathbf{B}}{c} \right) - \nabla \cdot \mathbb{P} + en_e \mathbb{R} \cdot \mathbf{J}, \quad (\text{A3})$$

where  $-e$  is the electron charge,  $n_e$  is the electron number density,  $\mathbf{V}_e$  is the electron fluid velocity,  $\mathbb{P}$  is the electron pressure tensor, and  $\mathbb{R}$  is the resistivity. The plasma is considered as quasi-neutral, such that

$$en_e = q_i n_i. \quad (\text{A4})$$

Electromagnetic fields are solved in the low frequency approximation. With the quasi-neutrality condition, Ampere's law becomes

$$\nabla \times \mathbf{B} = \frac{4\pi}{c} \mathbf{J} = \frac{4\pi}{c} q_i n_i (\mathbf{V}_i - \mathbf{V}_e), \quad (\text{A5})$$

where  $\mathbf{V}_i$  is the ion velocity, and Faraday's law is

$$\frac{\partial \mathbf{B}}{\partial t} = -c(\nabla \times \mathbf{E}), \quad (\text{A6})$$

and also

$$\nabla \cdot \mathbf{B} = 0. \quad (\text{A7})$$

Substitution of A5 into A3 removes  $\mathbf{V}_e$  and thus gives the equation for the electric field as

$$\mathbf{E} = -\frac{\mathbf{V}_i \times \mathbf{B}}{c} - \frac{(\nabla \times \mathbf{B}) \times \mathbf{B}}{4\pi n_e e c} - \frac{\nabla \cdot \mathbb{P}}{en_e} + \mathbb{R} \cdot \mathbf{J}. \quad (\text{A8})$$

Usually  $\mathbb{P}$  is taken to be a scalar,  $\mathbb{P} = p_e \mathbf{1}$ , with  $p_e = n_e T_e$  and an adiabatic law is assumed for the electron temperature  $T_e$ .  $\mathbb{R}$  is also usually taken as a scalar,  $\mathbb{R} = \eta \mathbf{1}$ .  $\mathbf{E}$  is then only a function of  $\mathbf{B}$ ,  $\mathbf{V}_i$ , and  $n_e$ .  $\mathbf{B}$  is advanced with a 4th order Runge-Kutta scheme using a smaller timestep than that for the particle push. Given  $\mathbf{B}$  and  $n_e$  advanced to the next time level,  $\mathbf{E}$  can be directly evaluated at the next time level if  $\mathbf{V}_i$  is known at that time. Finding the  $\mathbf{V}_i$  at the new time is the key feature of all hybrid algorithms [see *Winske et al.*, 2003, for details]. We use a simple Richardson extrapolation to get  $\mathbf{V}_i$  from its previously two saved values.

**Figure 1.** Magnetosheath density at two times during the simulations with  $n_s/n_m = 1$  for  $\theta_s = 0^\circ$  (left),  $15^\circ$  (middle) and  $30^\circ$  (right).

**Figure 2.** Magnetosheath density at two times during the simulations with  $n_s/n_m = 4$  for  $\theta_s = 0^\circ$  (left),  $15^\circ$  (middle) and  $30^\circ$  (right).

**Figure 3.** Magnetosheath density at two times during the simulations with  $n_s/n_m = 10$  for  $\theta_s = 0^\circ$  (left),  $15^\circ$  (middle) and  $30^\circ$  (right).

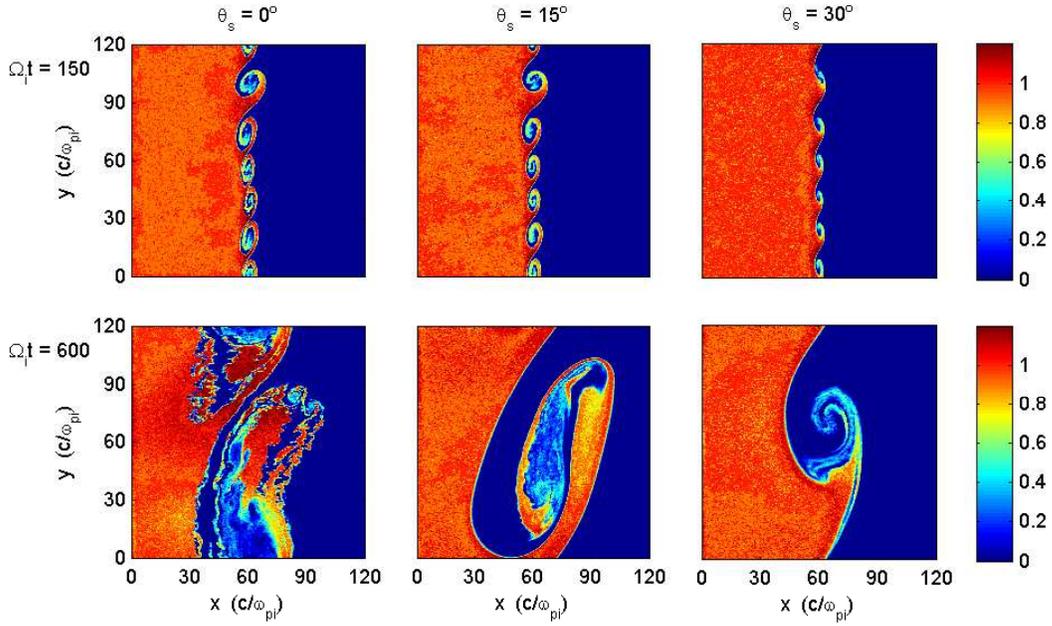

**Figure 4.** Simulated quantities in the grid cells along the  $y$  direction at  $x = 60c/\omega_{pi}$  at  $\Omega_i t = 150$  for the simulation with  $n_s/n_m = 1$  and  $\theta_s = 15^\circ$ . Shown are the density, parallel temperature,  $v(x, y)$  vectors,  $B(x, y)$  vectors, and  $B_z$ .

**Figure 5.** Simulated quantities in the grid cells along the  $y$  direction at  $\Omega_i t = 150$  for the simulation with  $n_s/n_m = 4$  and  $\theta_s = 15^\circ$ . Shown are the density, parallel temperature,  $v(x, y)$  vectors,  $B(x, y)$  vectors, and  $B_z$ .

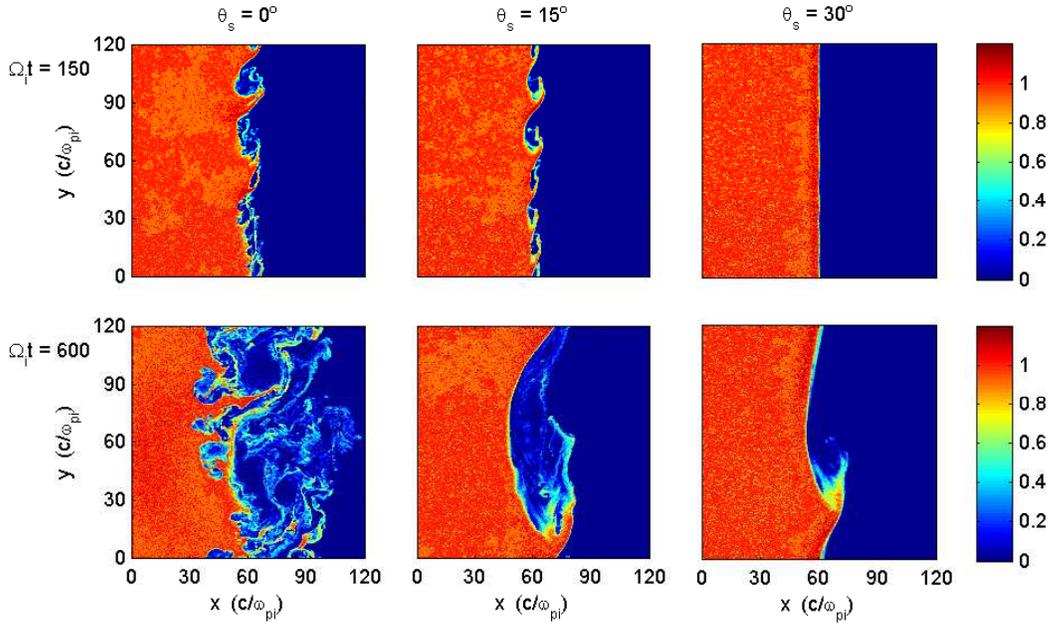

**Figure 6.** Simulated quantities in the grid cells along the  $y$  direction at  $\Omega_i t = 150$  for the simulation with  $n_s/n_m = 10$  and  $\theta_s = 15^\circ$ . Shown are the density, parallel temperature,  $v(x, y)$  vectors,  $B(x, y)$  vectors, and  $B_z$ .

**Figure 7.** Simulated bulk  $v_y$  versus density at  $\Omega_i t = 300$  for the simulations with  $n_s/n_m = 4$  (top) and  $n_s/n_m = 10$  (bottom) for  $\theta_s = 0^\circ$  (light gray) and  $\theta_s = 15^\circ$  (dark gray).

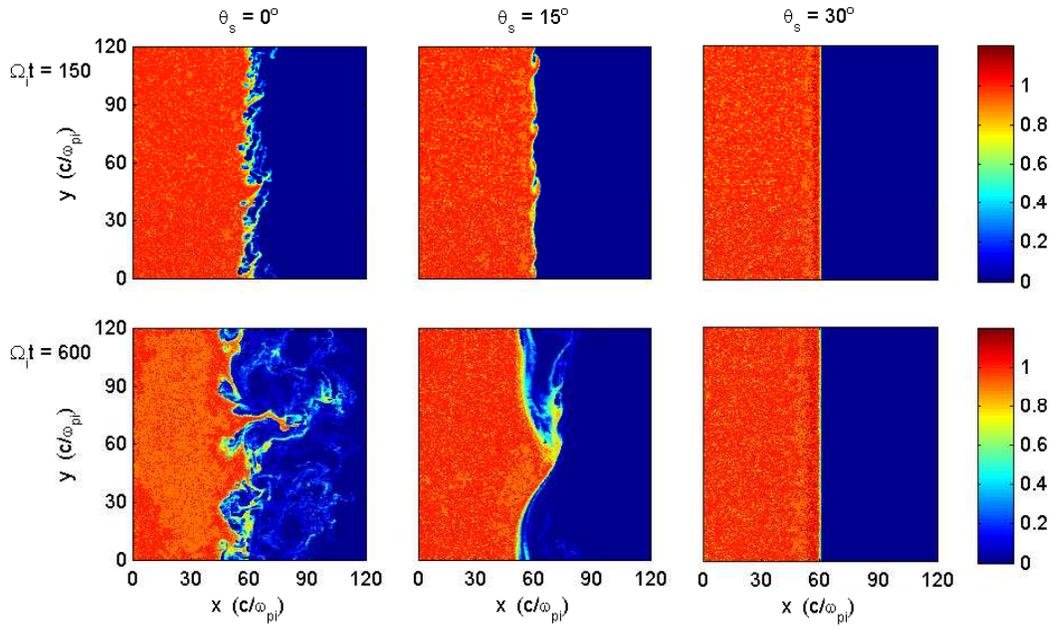

**Figure 8.** (Left) Mean-square displacement and (right) diffusion coefficients for the various simulations. Diffusion coefficients equivalent to  $10^8$  m<sup>2</sup>/s and  $10^9$  m<sup>2</sup>/s are indicated by the dotted and dot-dash lines, respectively.
